Abstract—We have fabricated large-aperture photoconductive antennas with interdigitated microstructured electrodes. The emitter was fabricated on a semi-insulating GaAs substrate and composed of seven units which can be operated independently, and the overall area was about 7 square cm. The spacing between each electrode was 10 micrometer. The device was operated at a bias voltage below 30 V. The obtained amplitude of the output THz waves was comparable to those from conventional large-aperture emitters. Coherent superposition of the output from each unit was observed.

I. INTRODUCTION

Large-aperture photoconductive antennas excited by amplified femtosecond optical pulses have been studied and used for the generation of intense terahertz (THz) pulses [1]-[5]. They can emit half-cycle or monocyte intense THz pulses with a broad bandwidth, and have been used in real-time imaging [5]-[9] and other applications. The requirement, however, of a bias voltage as high as 10 kV or more with conventional large-aperture emitters has limited their usage.

We fabricated microstructured photoconductive antenna arrays with interdigitated electrodes which can overcome limitation of the conventional structure.

The THz field is scaled to the effective emitter area and the bias field under pump fluences sufficiently large for saturation. Bias field applied to small spacings between microstructured electrodes can easily be raised up to a 100 kV/cm level, and 500 kV/cm will be possible using the state-of-the-art microprocessing technology. In contrast, the bias field of the conventional large-aperture antenna has been limited at around 10 kV/cm due to discharge on the semiconductor surface. Although the effective emitter area of the microstructured antenna is about 25% of the whole area, it is easily scalable using larger wafers. Thus the microstructured antenna is the choice for the generation of intense broadband THz pulses.

II. EMITTER STRUCTURE

The fabricated antenna array was composed of seven units of photoconductive antennas. They were fabricated on a 2-inch semi-insulating GaAs wafer. A picture of the whole emitter is shown in Fig. 1(a). Each unit had separate electrodes and could be operated independently. Each unit had metal interdigitated electrodes as shown in Fig. 1(b). The line width and the separation of the electrodes were both 10 µm, and each unit had an area of 10 mm x 10 mm. Shadow masks were placed to allow excitation light to irradiate only every other electrode spacing. This enables constructive interference of the THz field emitted from the interdigitated electrode structure. SiO₂ was deposited on the electrodes for the insulation between the electrodes and the metal shadow masks. The electrode structure was fabricated using two methods, i.e., lift-off and dry etching. Since the THz emission properties of these samples were found to be similar to each other, the experimental results obtained using only lift-off samples will be shown below.

Our device structure essentially follows the approach of Yoneda et al. [6] and Dreyhaupt et al. [7]. Yoneda et al.
fabricated an interdigitated antenna array on a CVD diamond substrate, which was excited by high-power KrF excimer laser pulses. The emitter of Dreyhaupt et al. had a size much smaller than the present one and was excited by unamplified laser pulses. The emitter reported in the present study had a size comparable to those of conventional large-aperture antennas, and was excited by amplified femtosecond Ti:sapphire laser pulses.

III. EXPERIMENTAL RESULTS

The properties of the emitter were characterized by measuring the waveforms of the emitted THz field as a function of bias voltage and excitation light fluence. The results were compared with those of a conventional large-aperture antenna [1], which had a 3-cm spacing between the electrodes. The antennas were excited by amplified 150-fs, 800-nm Ti:sapphire laser pulses at a repetition rate of 1 kHz. Emitted THz field was focused by a TPX lens of a 98.3-mm focal length, and the field waveform was measured using an electro-optic sampling method. The microstructured antenna was biased by a dc voltage up to 30 V, which corresponds to a bias field of 30 kV/cm. It was observed that the THz field becomes unstable above this voltage level. The obtained peak THz field at this bias was about half of that obtained using a conventional large-aperture antenna at a bias field of 2 kV/cm, as shown in Fig. 2. This is about seven times lower than predicted by a scaling law. The waveform of the THz pulse from the microstructured emitter shows a monocycle profile, which is in contrast to the half-cycle pulse shape obtained from the conventional large-aperture antenna.

In a separate measurement, a THz waveform from each unit was obtained by applying a voltage only to a single unit. It was found that the summation of the seven waveforms agreed with the waveform obtained from the whole antenna. This observation confirms coherent superposition of the THz waves from separate units.

IV. CONCLUSION

A large-aperture microstructured photoconductive antenna array having 10-µm width and spacing of interdigitated electrodes was fabricated on semi-insulating GaAs, and the properties were characterized. Generation of THz pulses with a field amplitude comparable to those obtained with conventional large-aperture antennas was observed. The obtained field was not as high as expected from the scaling law, and the properties will be improved by optimizing the microprocessing procedure. Coherent superposition of the output from each unit was observed.
